Abstract. The depolarization ratio is a valuable parameter for lidar-based aerosol categorization. Usually, the aerosol particle depolarization ratio is determined at relatively short wavelengths of 355 nm and/or 532 nm, but some multi-wavelength studies including longer wavelengths indicate strong spectral dependency. Here, we investigate the capabilities of Halo Photonics StreamLine Doppler lidars to retrieve the particle linear depolarization ratio at the 1565 nm wavelength. We utilize collocated measurements with another lidar system, PollyXT at Limassol, Cyprus, and at Kuopio, Finland, to compare the depolarization ratio observed by the two systems. For mineral-dust-dominated cases we find typically a slightly lower depolarization ratio at 1565 nm than at 355 and 532 nm. However, for dust mixed with other aerosol we find a higher depolarization ratio at 1565 nm. For polluted marine aerosol we find a marginally lower depolarization ratio at 1565 nm compared to 355 and 532 nm. For mixed spruce and birch pollen we find a slightly higher depolarization ratio at 1565 nm compared to 532 nm. Overall, we conclude that Halo Doppler lidars can provide a particle linear depolarization ratio at the 1565 nm wavelength at least in the lowest 2–3 km above ground.

1 Introduction

Aerosols and their interactions with clouds remain the largest source of uncertainty in the Earth's radiative budget (IPCC, 2013). Remote sensing measurements with lidars enable continuous long-term observations of the vertical distribution of aerosol particles and clouds in the atmosphere, providing valuable information for improving our understanding of the global climate system (e.g. Illingworth et al., 2015). Information on the vertical distribution of aerosols is highly important also for the aviation industry in case of hazardous aerosol emissions from for example volcanic eruptions (Hirtl et al., 2020).

Lidar measurements of aerosol optical properties at multiple wavelengths can be used to categorize elevated aerosol layers into different types such as mineral dust, smoke, marine aerosol or volcanic ash (e.g. Baars et al., 2017; Papa- giannopoulos et al., 2018). One of the most important parameters for such aerosol typing is the depolarization ratio, which enables distinguishing spherical and non-spherical particles from each other (e.g. Burton et al., 2012; Baars et al., 2017). Furthermore, the depolarization ratio can be used to quantify the contributions of different aerosol types to elevated layers (Mamouri and Ansmann, 2017). It is essential also for esti-

inating vertical profiles of cloud condensation nuclei (CCN) and ice-nucleating particle (INP) concentrations from remote sensing observations (Mamouri and Ansmann, 2016).

Currently, the particle linear depolarization ratio is most commonly measured at relatively short wavelengths of 355 and/or 532 nm (e.g. Illingworth et al., 2015; Baars et al., 2016), though some lidar systems are capable of depolarization ratio measurement at longer wavelengths of 710 and 1064 nm (e.g. Freudenthaler et al., 2009; Burton et al., 2012). For instance, Burton et al. (2012) used the ratio of depolarization ratios at 1064 and 532 nm as part of their aerosol typing procedure. However, to our knowledge, the aerosol particle depolarization ratio has not been reported at wavelengths longer than 1064 nm.

Previous studies on the spectral dependency of the depolarization ratio between 355 and 1064 nm have shown a steep decrease in the depolarization ratio from 532 to 1064 nm for elevated biomass burning aerosols (Burton et al., 2012, 2015; Haarig et al., 2018; Hu et al., 2019). On the contrary, mineral dust layers present an increasing depolarization ratio with increasing wavelength (Groß et al., 2011; Burton et al., 2015) or a relatively weak maximum at 532 nm (Freudenthaler et al., 2009; Burton et al., 2015; Haarig et al., 2017). For some aerosol types, such as marine aerosol (Groß et al., 2011) and volcanic ash (Groß et al., 2012), no spectral dependency was observed. However, volcanic ash mixed with boundary layer aerosol was observed with a clearly lower depolarization ratio at 355 nm than at 532 nm (Groß et al., 2012).

The spectral dependency of the depolarization ratio has been attributed largely to the shape of the size distribution of polarizing aerosol particles. In smoke layers, the depolarization signal is probably due to non-spherical soot aggregates, which are in the size range of 100 nm to hundreds of nanometres and thus do not produce a large depolarization ratio at 1064 nm (Burton et al., 2015; Haarig et al., 2018; Hu et al., 2019). Recently, Gialitaki et al. (2020) modelled smoke as near-spherical submicron particles and found good agreement with the observed spectral dependency of the depolarization ratio. On the other hand, mineral dust contains significant amounts of coarse-mode particles ($> 1 \mu\text{m}$ in diameter), which can explain the large depolarization ratio also observed at the 1064 nm wavelength (Freudenthaler et al., 2009; Groß et al., 2011; Burton et al., 2015; Haarig et al., 2017). In aged dust layers, the faster removal of supermicron particles is thought to result in the depolarization ratio peaking at 532 nm (Freudenthaler et al., 2009; Groß et al., 2011; Burton et al., 2015; Haarig et al., 2017). In other words, spectral analysis of the depolarization ratio could permit more in-depth diagnosis of coarse-mode polarizing aerosol.

Halo StreamLine Doppler lidars are commercially available fibre-optic systems that operate at a wavelength of 1565 nm and can be equipped with a cross-polar receiver channel for measuring the depolarization ratio (Pearson et al., 2009). Over the last few years these lidars have become widely used in wind and turbulence studies (e.g. Päsche et

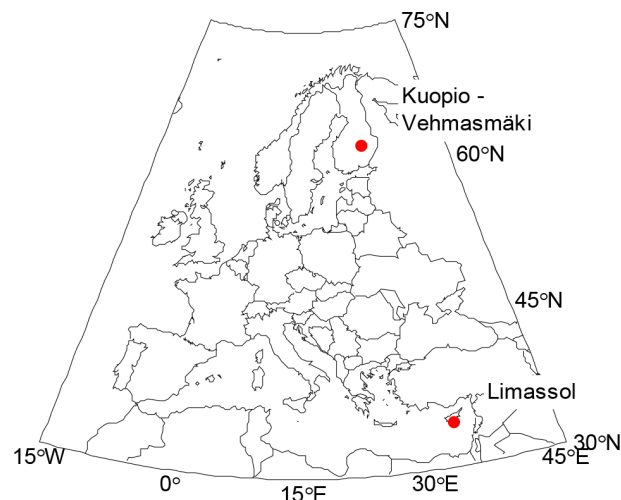

Figure 1. Locations of Vehmasmäki and Limassol measurement sites.

al., 2015; Vakkari et al., 2015; Tuononen et al., 2017; Manninen et al., 2018). Additionally, depolarization ratio measurements by Halo lidars have been used to study cloud and precipitation phase (e.g. Achtert et al., 2015).

Now, recently developed post-processing (Vakkari et al., 2019) allows the utilization of significantly weaker signals from Halo Doppler lidars than previously. Therefore, the main aim of this paper is to assess the capabilities of Halo Doppler lidars in providing particle linear depolarization ratio measurements at the 1565 nm wavelength. To do so, we utilize collocated Halo Doppler lidar and multiwavelength Raman lidar PollyXT observations during two measurement campaigns, where different polarizing aerosols were observed. Overall, the comparison indicates that Halo Doppler lidars can add another wavelength at 1565 nm to studies on the spectral dependency of the particle linear depolarization ratio, at least in the lowest 2–3 km above ground.

2 Materials and methods

Here we use data from two measurement campaigns where a Halo Photonics Doppler lidar and a PollyXT Raman lidar were collocated: at Kuopio, Finland, from 9 to 16 May 2016 and at Limassol, Cyprus, from 21 April to 22 May 2017. The campaigns represent quite different environments (Fig. 1) and enable the comparison of the depolarization ratio at 1565 nm by the Halo instrument to the depolarization ratio at 355 and 532 nm from PollyXT for a range of aerosol types. Furthermore, the campaigns were equipped with different devices of the Halo and PollyXT designs, and thus potential differences between instrument individuals can be investigated.

The Vehmasmäki site (62.738° N, 27.543° E; 190 m a.s.l.) in Kuopio is a rural location surrounded by boreal forest (Bohlmann et al., 2019). The focus of the campaign in

May 2016 was to investigate the capability to characterize the optical properties of airborne pollen with the multiwavelength Raman lidar PollyXT (Bohlmann et al., 2019). Here, we utilize 1 week of collocated measurements to compare Halo depolarization at 1565 nm to PollyXT during a spruce and birch pollination episode.

Limassol (34.675° N, 33.043° E; 22 m a.s.l.) is located at the southern shore of Cyprus in the eastern Mediterranean. Measurements at Limassol were part of the Cyprus Clouds Aerosol and Rain Experiment (CyCARE; Ansmann et al., 2019) and were performed as a collaboration between the Cyprus University of Technology (CUT), Limassol, and the Leibniz Institute for Tropospheric Research (TROPOS), Leipzig. During April–May, several Saharan dust episodes were observed at Limassol in addition to the regional aerosol.

2.1 Halo Doppler lidar

Halo Photonics StreamLine lidars are commercially available 1565 nm pulsed Doppler lidars equipped with a heterodyne detector (Pearson et al., 2009). Halo StreamLine lidars emit linearly polarized light, and the optical path is constructed with fibre-optic components, which can be equipped with a cross-polar receiver channel. The cross-polar channel is implemented through a fibre-optic switch between the normal receiver path and path with a fibre-optic polarizer. Thus, the measurement of the co- and cross-polar signals is not simultaneous but consecutive in vertically pointing mode. For instance, if the integration time per ray is set to 7 s, then co-polar signal is collected for 7 s and then cross-polar signal is collected during the next 7 s.

For research purposes, the most commonly used variants of StreamLine lidars are StreamLine, StreamLine Pro and StreamLine XR. The StreamLine and the more powerful StreamLine XR lidars enable full hemispheric scanning. The Streamline Pro is designed without moving parts on the outside, which limits the scanning to a cone of 20° from vertical. All StreamLine variants can be used for depolarization ratio measurements, but an important difference between XR and other StreamLine versions is that the XR background noise level cannot be determined as accurately in the near range as for the non-XR versions (Vakkari et al., 2019). This difference is attributed to the more sensitive amplifier used in the StreamLine XR (Vakkari et al., 2019).

In this study we utilize vertically pointing measurements only from two StreamLine Pro systems. The operating specifications of these systems are given in Table 1. StreamLine lidars send and receive pulses through a single lens, which avoids issues with overlap and leads to a minimum range of 90 m due to impact of the outgoing pulse. At Vehmasmäki, we focused on boundary layer aerosol and set integration time per ray to 7 s and telescope focus to 2000 m. At Limassol, we expected to encounter elevated aerosol layers frequently and set the integration time per ray to 11.5 s and telescope focus to infinity. The integration time is set to bal-

ance between signal strength and good enough time resolution for retrievals of turbulent properties.

Halo StreamLine lidars provide three parameters along the beam direction: radial Doppler velocity, signal-to-noise ratio (SNR) and attenuated backscatter (β), which is calculated from SNR taking into account the telescope focus. For a coherent Doppler lidar attenuated backscatter is obtained as

$$\beta(z) = A \frac{\text{SNR}(z)}{T_f(z)}, \quad (1)$$

where z is the range from the instrument, A incorporates system-specific constants and $T_f(z)$ is the telescope focus function, which includes range correction (Frehlich and Kavaya, 1991; Pentikäinen et al., 2020).

A background check to determine range-resolved background noise level is performed automatically once per hour. The raw signal from atmospheric measurement is then divided by this noise level in the firmware and returned as SNR (see Vakkari et al., 2019). We post-processed SNR according to Vakkari et al. (2019), which ensures that both co- and cross-polar SNR have an unbiased noise level; i.e. SNR is 0 when there is no signal (cf. Manninen et al., 2016). Furthermore, the post-processing is essential to be able to further reduce the instrumental noise floor by averaging the SNR (Vakkari et al., 2019). After post-processing SNR, β is calculated with Eq. (1).

Halo depolarization ratio

We estimate the instrumental uncertainty in Halo StreamLine SNR from the standard deviation of SNR in the cloud- and aerosol-free part of the profile. Given the long wavelength and low pulse energy, no contribution from molecular scattering is observed in the signal. At 1565 nm the molecular backscatter coefficient is about $1.9 \times 10^{-8} \text{ m}^{-1} \text{ sr}^{-1}$ at mean sea level, using mean values for the atmospheric number density taken from the US Standard Atmosphere, 1976 (COESA 1976). The two-way atmospheric transmittance at 1565 nm is still 0.9994 at 2 km altitude above a lidar situated at mean sea

Figure 2. Profiles at Limassol, Cyprus, on 2 May 2017 at 12:08 UTC. **(a)** Co- and cross-polar SNR. A liquid cloud at approx. 800 m a.g.l. results in full attenuation of signal. Below cloud layer aerosol signal is visible. Above 1 km variability in SNR is due to instrumental noise only. **(b)** The same as panel (a) but limited to lowest 1 km a.g.l. **(c)** Ratio of cross-polar SNR to co-polar SNR up to 1 km a.g.l. calculated from profiles in panel (a). Error bars represent uncertainty due to instrumental noise estimated from SNR at > 1 km a.g.l. in panel (a).

level. Hence, the measured depolarization ratio can be safely assumed to represent the particle linear depolarization ratio.

In Fig. 2a, consecutive co- and cross-polar SNR profiles are presented, where aerosol signal is observed up to 800 m above ground level (a.g.l.) and a liquid cloud base is observed at 840 m a.g.l. In liquid cloud the signal attenuates quickly, and above 1 km the profiles represent instrumental noise only. We use the measurements above 1 km to calculate standard deviations of co-polar SNR (σ_{co}) and cross-polar SNR (σ_{cross}). In Fig. 2c, the raw depolarization ratio (δ^*) is calculated simply as the ratio of cross-polar SNR to co-polar SNR, and uncertainty is estimated from σ_{co} and σ_{cross} by Gaussian error propagation.

The construction of Halo StreamLine lidars does not include a calibrator for depolarization channel, unlike PollyXT lidars for instance (Engelmann et al., 2016). Furthermore, the user cannot change the optical path to include a calibrator or check the depolarizing effects of the individual components. Therefore, we are limited to evaluating the Halo depolarization ratio at liquid cloud base.

Spherical cloud droplets do not polarize the directly backscattered radiation, and thus non-zero δ^* at liquid cloud base is an indication of incomplete extinction (or bleed-through) in the lidar internal polarizer. However, measurement of δ^* at cloud base can be biased by signal saturation or changes in cloud properties between co- and cross-polar measurement. Furthermore, multiple scattering results in increasing depolarization signal inside a liquid cloud (e.g. Liou and Schotland, 1971). This increase in in-cloud δ^* is clearly seen in Fig. 2c: at cloud base δ^* is 0.0102, and at the next gate 30 m deeper inside the cloud δ^* has increased to 0.0116.

The magnitude of the multiple scattering effect on depolarization ratio depends on both cloud and lidar properties

(e.g. Donovan et al., 2015). In Halo StreamLine lidars the instrument telescope design has a matched field of view and divergence of $33 \mu\text{rad}$ (Table 1), and consequently the effect is small: in Fig. 2c δ^* increases by 0.0014 in 30 m. For instance, for the system modelled by Donovan et al. (2015) in-cloud multiple scattering increases the depolarization ratio from 0 to 0.05 in approx. 50 m. Nevertheless, to minimize the effect of multiple scattering we only consider δ^* at the cloud base for the determination of the average bleed-through and use measurements in several clouds.

For low-level clouds, we have observed saturation of the co-polar signal in the more powerful StreamLine XR instruments. Signal saturation at liquid cloud base is readily identified as a non-linear relationship between co- and cross-polar SNR. For the measurement cases analysed here, we did not observe indications of saturation. Furthermore, we note that δ^* at cloud base should be determined with as high a time resolution as possible to ensure that both co- and cross-polar measurements represent the same part of the cloud. In practice, integration time is kept constant during a measurement campaign and was set as a compromise between temporal resolution and signal strength. We mitigate the effect of poor time resolution by choosing cases where cloud base remains at the same altitude (within lidar resolution) for some tens of minutes and thus one can assume temporal homogeneity. No vertical smoothing is applied in calculating δ^* , as the signal at cloud base is strong compared to the aerosol signal. Finally, it should be noted that, especially in higher latitudes, it is not always trivial to find purely liquid phase clouds. Typically, mixed-phase clouds can be distinguished by the depolarizing features of ice crystals. That is, in the histogram of δ^* at cloud base a secondary peak with higher δ^* than liquid clouds would occur, which was not the case for our study.

To characterize the Halo polarizer bleed-through, we determined the δ^* at liquid cloud base during both campaigns (Fig. 3). During the campaign at Limassol, we determined δ^* at cloud base on 25 April and on 2 May 2017. From the distribution in Fig. 3a, the bleed-through is 0.011 ± 0.007 (mean \pm standard deviation). At Vehmassäki, we utilized clouds on 13, 14 and 16 May 2016 as shown in Fig. 3b. At Vehmassäki, the estimated bleed-through is 0.016 ± 0.009 (mean \pm standard deviation). The mean cloud base δ^* values observed for these two systems in Fig. 3 are well in line with our experience with these and five other StreamLine and StreamLine XR systems in Finland, where cloud base δ^* typically ranges from 0.01 to 0.02.

We attribute the spread in the distributions in Fig. 3 mostly to variability of the clouds at the measurement sites and to the fact that co- and cross-polar measurements are consecutive and not simultaneous. Given that the cross-polar measurement channel is constructed with fibre-optic technology, we do not expect changes in the performance of the polarizer. This is also our experience with Halo systems in Finland since 2016, but we recommend to check the bleed-through monthly or after an instrument is moved to a new location.

Figure 3. Ratio of cross-polar SNR to co-polar SNR at liquid cloud base measured with Halo Doppler lidar. **(a)** Distribution of cloud base δ^* at Limassol. **(b)** Distribution of cloud base δ^* at Vehmasmäki.

Considering the large natural variability of the depolarization ratio (e.g. Illingworth et al., 2015; Baars et al., 2016) we find the spread of observations in Fig. 3 tolerable. The standard deviation in Fig. 3 is included in the uncertainty calculation of the Halo depolarization ratio.

We account for the observed bleed-through (B) in calculating Halo particle linear depolarization ratio (δ_{1565}) as

$$\delta = \frac{\text{SNR}_{\text{cross}} - B \cdot \text{SNR}_{\text{co}}}{\text{SNR}_{\text{co}}}, \quad (2)$$

where SNR_{co} and $\text{SNR}_{\text{cross}}$ are the observed co- and cross-polar SNR, respectively. Uncertainty in $\text{SNR}_{\text{cross}}$ corrected for bleed-through (i.e. numerator in Eq. 2) is estimated as

$$\sigma_{\text{cross}, B} = \sqrt{\sigma_{\text{cross}}^2 + (B \cdot \text{SNR}_{\text{co}})^2 \cdot \left(\frac{\sigma_B^2}{B^2} + \frac{\sigma_{\text{co}}^2}{\text{SNR}_{\text{co}}^2} \right)}, \quad (3)$$

where σ_B is standard deviation of the distribution in Fig. 3. Finally, uncertainty in δ_{1565} taking into account instrumental noise and uncertainty in bleed-through is estimated as

$$\sigma_{\delta} = |\delta| \sqrt{\frac{\sigma_{\text{cross}, B}^2}{(\text{SNR}_{\text{cross}} - B \cdot \text{SNR}_{\text{co}})^2} + \frac{\sigma_{\text{co}}^2}{\text{SNR}_{\text{co}}^2}}. \quad (4)$$

2.2 PollyXT

PollyXT is a multiwavelength Raman lidar capable of depolarization ratio measurement at one or two wavelengths depending on instrument configuration (Baars et al., 2016; Engelmann et al., 2016). PollyXT emits simultaneously 355, 532 and 1064 nm wavelength pulses at a repetition frequency of 20 Hz. All PollyXT lidars are built with the same design, but there are small differences in the number of receiver channels equipped in each individual system. A detailed description of PollyXT design is given by Baars et al. (2016) and Engelmann et al. (2016).

At Vehmasmäki, PollyXT was configured with elastic backscatter channels (355, 532 and 1064 nm); Raman-shifted channels at 387, 407 and 607 nm; and a cross-polar channel

at 532 nm (Bohmann et al., 2019). Due to the biaxial construction of emission and detection units, complete overlap is reached at 800–900 m a.g.l. (Engelmann, et al., 2016), and thus only measurements >800 m a.g.l. are utilized for this study (Bohmann et al., 2019). The original spatial resolution is 30 m and temporal resolution 30 s for the Vehmasmäki system (Bohmann et al., 2019).

At Limassol, PollyXT operated the same receiver channels as the Vehmasmäki system had and additionally a cross-polar channel at 355 nm, together with a near-range telescope with 355 and 532 nm receiver channels. The near-range channels enable retrieval of optical properties down to 150 m a.g.l. (Engelmann et al., 2016). Raw spatial resolution is 7.5 m and temporal resolution is 30 s.

During night-time, the Raman method (Ansmann et al., 1992) is used to retrieve aerosol optical properties from the raw signals. For daytime measurements, the method of Klett (1981) can be utilized. Here, we present only measurements when the Raman method was applied. The calibration of the depolarization ratio was performed at both Vehmasmäki and Limassol using the so-called $\Delta 90^\circ$ method (Freudenthaler, 2016), and the relative uncertainty in the particle linear depolarization ratio was estimated to be 10 %.

2.3 Auxiliary data

Air mass history was estimated with the Hybrid Single-Particle Lagrangian Integrated Trajectory model, HYSPPLIT (Stein et al., 2015). HYSPPLIT was run through the READY website (Rolph et al., 2017) using the NCEP Global Data Assimilation System (GDAS) meteorology at 0.5° horizontal resolution. Back trajectories of 96 h arriving at the elevation of aerosol layers of interest were calculated.

3 Results

In this section we analyse observations of dust, marine and pollen aerosols during the Limassol and Vehmasmäki campaigns, where said aerosol types were observed simultaneously with Halo and PollyXT lidars. Dust and marine aerosols were observed during the Limassol campaign in the eastern Mediterranean, and pollen was observed during the Vehmasmäki campaign in a boreal forest region in Finland. We conclude this section with an overall comparison of the depolarization ratio measurements with the two instruments.

3.1 Elevated dust layers

3.1.1 Limassol 21 April 2017

Right at the beginning of Halo measurements at Limassol on 21 April 2017, several elevated layers were observed as seen in Fig. 4. Although Halo can observe elevated layers up to 6 km a.g.l. on this day, the signal is too weak to retrieve their depolarization ratio. This is clearly visible in the uncer-

Figure 4. Limassol 21 April 2017 measurements with Halo Doppler lidar. (a) Time series of co-polar SNR at 300 s integration time. (b) Time series of cross-polar SNR at 300 s integration time. (c) Uncertainty in the depolarization ratio. (d) Particle linear depolarization ratio filtered with $\sigma_\delta < 0.05$.

tainty in the Halo depolarization ratio in Fig. 4c. At 300 s integration time (i.e. 10 min of alternating co- and cross-polar measurement), the depolarization ratio can be determined up to 1–1.5 km a.g.l. with $\sigma_\delta < 0.05$ on this day (Fig. 4d). The depolarization ratio can be retrieved also for the relatively strong elevated layer at 3 km a.g.l. during the morning hours (Fig. 4d).

Increasing both temporal and spatial averaging enables the utilization of some of the weaker signals. Figure 5 presents profiles of the Halo and PollyXT depolarization ratio, where both are averaged over 1.5 h (20:00–21:30 UTC) and smoothed vertically with a 300 m running mean. In the lowest layer < 1 km a.g.l., practically no difference is observed in the depolarization ratio at the different wavelengths. Back-trajectory calculations (Fig. 6) indicate this layer to be mostly regional air from eastern Mediterranean, and the relatively large lidar ratio is in the range of observations of smoke or smoke mixed with dust (e.g. Groß et al., 2011; Baars et al., 2016). On the other hand, for the layer from 1.5 km to 2 km a.g.l. a clear increase in δ with increasing wavelength is observed. For this layer air mass history indicates origins over northern Africa (Fig. 6), and the lidar ratio (42 ± 4 at 355 nm, 47 ± 5 at 532 nm) is in the range of dust (Ansmann et al., 2011). For this layer the mean (\pm standard deviation) δ values at 355, 532 and 1565 nm are 0.19 ± 0.008 , 0.23 ± 0.008 and 0.29 ± 0.008 , respectively. Above 2 km a.g.l., the uncertainty in δ at 1565 nm increases rapidly and is not used for quantitative analysis here.

3.1.2 Limassol 27 April 2017

Stronger elevated aerosol layers were observed at Limassol on 27 April 2017. On this day, the depolarization ratio can be retrieved by Halo up to 3 km a.g.l. (Fig. 7). For an averaging period of 01:25–02:30 UTC, the depolarization ratio

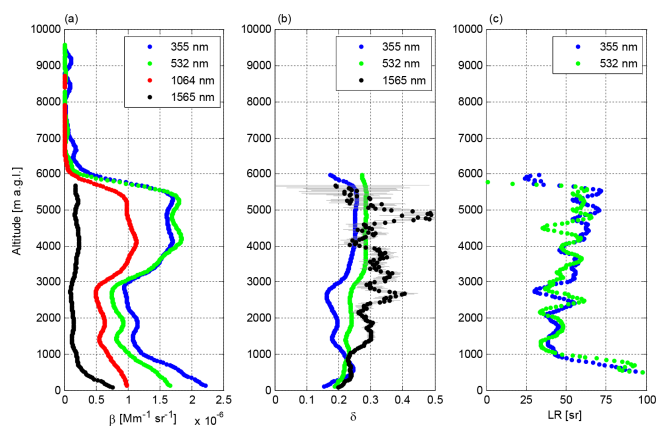

Figure 5. Averaged profiles at Limassol on 21 April 2017 at 20:00–21:30 UTC. All profiles have been smoothed by a 300 m running mean. (a) Backscatter by PollyXT (wavelengths 355–1064 nm) and attenuated backscatter by Halo (1565 nm). (b) Particle linear depolarization ratio. Error bars represent measurement uncertainty. (c) Lidar ratio. For PollyXT β_{355} , β_{532} , LR_{355} and LR_{532} , a near-range telescope is used for data < 900 m a.g.l.

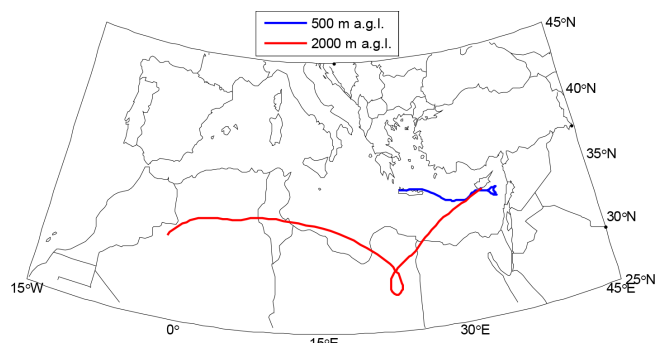

Figure 6. Back trajectories of 96 h arriving at Limassol on 21 April 2017 at 21:00 UTC.

is retrieved for the elevated layer at 1600–2200 m a.g.l. For this layer, the depolarization ratio at 1565 nm is 0.30 ± 0.005 , which is a little lower than for the shorter wavelengths: 0.36 ± 0.01 at 355 nm and 0.34 ± 0.002 at 532 nm, respectively. For this layer, the air mass history indicates southerly origins.

On the same day (27 April 2017) at 19:00–20:00 UTC, the depolarization ratio can be retrieved from the surface up to 2.6 km a.g.l. (Fig. 8). In the lowest 500 m, the depolarization ratio at 1565 nm is clearly higher than at the shorter wavelengths, suggesting a mixture of larger mineral dust particles with smaller particles of a lower depolarization ratio. For the layer at 1500–2500 m a.g.l., practically no wavelength dependency is observed for the depolarization ratio, indicating that backscatter at all wavelengths is dominated by the same aerosol. The layer-averaged depolarization ratios are 0.31 ± 0.006 , 0.33 ± 0.005 and 0.32 ± 0.008 at 355, 532 and 1565 nm, respectively. The high depolarization ratio and li-

dar ratio of 47 ± 5 at 355 nm (38 ± 3 at 532 nm) indicate almost pure dust (Ansmann et al., 2011; Baars et al., 2016). Air mass history, on the other hand, indicates northerly or north-westerly origins at both 2 km a.g.l. and at the surface (Fig. 9).

3.2 Polluted marine aerosol

On 20 May 2017 at Limassol, a very low aerosol depolarization ratio is observed throughout the day as seen in Fig. 10. During the morning and afternoon liquid clouds are observed, but during the evening Raman retrievals with PollyXT were possible. Figure 11 presents Halo depolar-

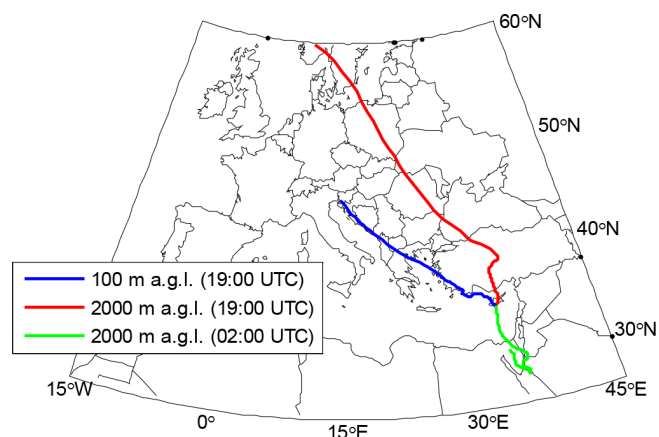

Figure 9. Back trajectories of 96 h arriving at Limassol on 27 April. Back trajectories arriving at 19:00 and 02:00 UTC are included.

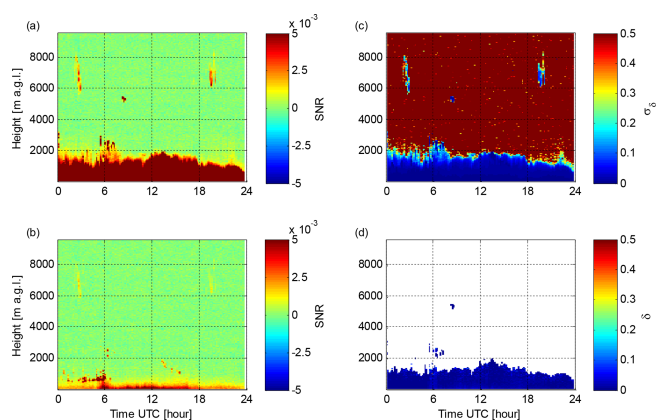

Figure 10. Limassol 20 May 2017 measurements with Halo Doppler lidar. (a) Time series of co-polar SNR at 300 s integration time. (b) Time series of cross-polar SNR at 300 s integration time. ization ratio profiles averaged for the duration of the PollyXT retrieval at 19:54–21:30 UTC. For the surface layer (up to 1 km a.g.l.), a small decrease in the depolarization ratio with increasing wavelength is observed. The layer-averaged depolarization ratios are 0.03 ± 0.01 , 0.015 ± 0.002 and 0.009 ± 0.003 at 355, 532 and 1565 nm, respectively. The layer-averaged lidar ratio at 355 nm is 39 ± 4 sr, whereas the lidar ratio at 532 nm is very noisy at 47 ± 35 sr. The low depolarization ratio is typical of marine aerosol, smoke and pollution (Groß et al., 2011; Illingworth et al., 2015). The 355 nm lidar ratio lies between the values reported for marine aerosol and smoke (Illingworth et al., 2015).

Above 1 km a.g.l., an optically thin aerosol layer is observed (Fig. 11). Halo indicates a higher depolarization ratio for this layer than at the surface, but the signal is so weak that the uncertainty in the depolarization ratio at 1565 nm becomes very large (Fig. 11b). Back trajectories arriving

over Limassol at 21:00 UTC indicate different but mostly northerly origins for the air mass at 500 m and at 2 km a.g.l. (Fig. 12).

3.3 Pollen in boreal forest

On 15 May 2016, substantial amounts of spruce and birch pollen were observed at Vehmassmäki with both an in situ sampler and the PollyXT lidar (Bohlmann et al., 2019). The presence of more polarizing spruce pollen (Bohlmann et al., 2019) in the boundary layer is observed also with Halo lidar as seen in Fig. 13d. However, the backscatter (Fig. 14a) is low compared to the case studies presented for Limassol, and the low signal results in significant noise in the lidar ratio (Fig. 14c).

Comparing the depolarization ratios measured with Halo and PollyXT (Fig. 14b) shows a nearly constant depolariza-

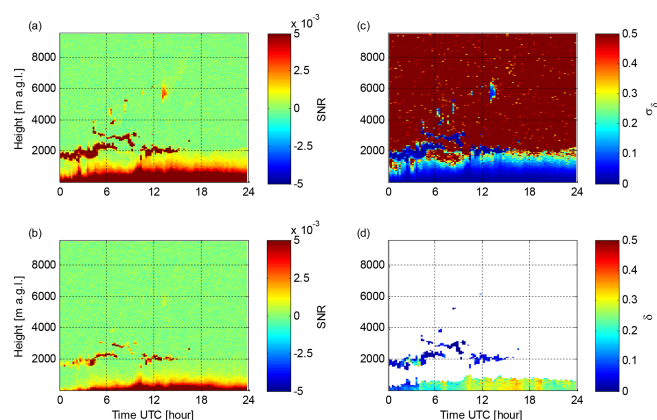

Figure 13. Vehmassmäki 15 May 2016 measurements with Halo Doppler lidar. (a) Time series of co-polar SNR at 350 s integration time. (b) Time series of cross-polar SNR at 350 s integration time. (c) Uncertainty in the depolarization ratio. (d) Particle linear depolarization ratio filtered with $\sigma_{\delta} < 0.05$.

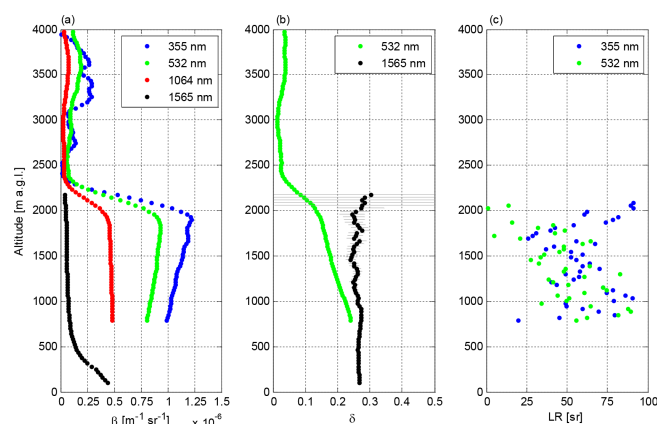

Figure 14. Averaged profiles at Vehmassmäki on 15 May 2016 at 19:00–21:00 UTC. All profiles have been smoothed by a 300 m running mean. (a) Backscatter by PollyXT (wavelengths 355–1064 nm) and attenuated backscatter by Halo (1565 nm). (b) Particle linear depolarization ratio. Error bars represent measurement uncertainty. (c) Lidar ratio.

tion ratio at 1565 nm, while the depolarization ratio at 532 nm decreases with height. At 1565 nm, the Halo signal is probably dominated by pollen grains, which are tens of micrometres in diameter. At the 355 and 532 nm wavelengths, the backscatter is increasing with height (Fig. 14a), and thus the decreasing depolarization ratio at 532 nm may reflect an increasing fraction of signal from non-pollen aerosol with increasing height. For the layer from 800 m to 1 km a.g.l. in Fig. 14, the mean depolarization ratios are 0.236 ± 0.009 and 0.269 ± 0.005 at 532 and 1565 nm, respectively.

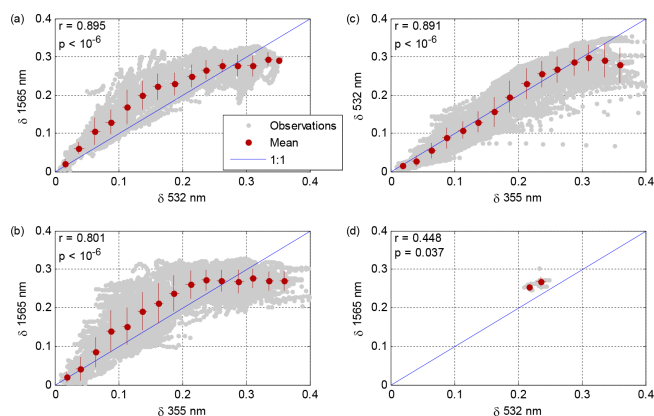

Figure 15. Comparison of particle linear depolarization ratio at different wavelengths. Observations represent 30 m vertical resolution and have been smoothed by a 300 m running mean. To reduce scatter, a stricter uncertainty threshold is applied, and only data for $\sigma_{\delta} < 0.01$ (at the 1565 nm wavelength) are included. The mean is calculated at intervals of 0.025 on the x axis, and error bars indicate standard deviation. (a) Depolarization ratio at 1565 nm (Halo) vs. depolarization ratio at 532 nm (PollyXT) at Limassol. (b) Depolarization ratio at 1565 nm vs. depolarization ratio at 355 nm (PollyXT) at Limassol. (c) Depolarization ratio at 532 nm vs. depolarization ratio at 355 nm at Limassol. (d) Depolarization ratio at 1565 nm vs. depolarization ratio at 532 nm at Vehmasmäki.

3.4 Overview of depolarization ratio wavelength dependency

An overall comparison of the depolarization ratio at different wavelengths for the Limassol and Vehmasmäki campaigns is presented in Fig. 15, where the Halo vertical resolution of 30 m has been smoothed with a 300 m running mean. The original time resolution observations by Halo have been averaged to match the temporal resolution of PollyXT Raman retrievals (ranging from 45 min to 2 h).

In Fig. 15a, three regions can be observed in the scatterplot. For $\delta_{532} < 0.05$, δ_{1565} matches very closely with the shorter wavelength. For δ_{532} ranging from 0.05 to 0.25, δ_{1565} is systematically larger than δ_{532} . For $\delta_{532} > 0.3$, δ_{1565} is lower than the depolarization ratio at the shorter wavelength. A very similar pattern is present in Fig. 15b: for $\delta_{355} < 0.05$, δ_{1565} matches δ_{355} closely; for δ_{355} ranging from 0.05 to 0.25, δ_{1565} is larger than δ_{355} ; and for $\delta_{355} > 0.3$, δ_{1565} is lower than δ_{355} . Similar regions appear even when comparing the two shorter wavelengths (Fig. 15c): for $\delta_{355} < 0.05$, δ_{532} is lower than δ_{355} ; for δ_{355} ranging from 0.1 to 0.3, the depolarization ratio is on average equal on both wavelengths; and for $\delta_{355} > 0.3$, δ_{532} is lower than δ_{355} .

Figure 15a–c also show similar correlations between the depolarization ratios at different wavelengths. Therefore, bearing in mind the similar patterns in all three scatterplots in Fig. 15a–c, we consider the scatter to originate mainly from the atmospheric aerosol properties rather than in instrumental

effects. For instance, any bias in the estimated bleed-through in the Halo polarizer would show up as bias in Fig. 15a and b. However, such bias is not present in the cases when δ_{355} and/or δ_{532} are low.

Considering the sources at Limassol during the campaign, the higher δ_{1565} for intermediate depolarization ratios ranging from 0.1 to 0.25 likely represents mixtures of dust with other aerosol types. A mixture of coarse, polarizing dust with less polarizing and smaller aerosol would result in the observed spectral dependency of the depolarization ratio. For aged-dust-dominated cases, lower depolarization ratios at longer wavelength could be due to the faster removal of coarse particles compared to submicron aerosol (e.g. Burton et al., 2015). In any case, the observed wavelength dependency in Fig. 15a–c for large δ suggests that, for dust-dominated cases, smaller particle sizes have, on average, a higher depolarization ratio at Limassol.

Another type of polarizing aerosol, i.e. pollen, was observed with a collocated Halo and PollyXT at Vehmasmäki (Bohlmann et al., 2019). Comparatively low signal levels, together with 800 m minimum range for the PollyXT system at Vehmasmäki (Bohlmann et al., 2019), reduce the amount of data available for comparison of Halo and PollyXT depolarization ratio during the campaign (Fig. 15d). During this campaign, the depolarization ratio at 1565 nm is a little larger than at 532 nm, but the difference is small compared to the scatter observed at Limassol.

A further look into the distribution and spectral dependency of the depolarization ratio at Limassol is presented in Fig. 16. In Fig. 16a and b, the 2D histograms of the depolarization ratio show that both the 532 and 1565 nm wavelengths present a bi-modal distribution below 1 km a.g.l. In other words, there are also less polarizing aerosols frequently present in the lowest 1 km in addition to dust and dusty mixtures with a depolarization ratio > 0.2 . However, above about 1.5–2 km a.g.l., almost all retrievals indicate dust or dusty mixtures. Note that the vertical extent of the data is limited by the sensitivity of the Halo instrument, as Fig. 16a and b are limited to cases when both wavelengths are available.

In Fig. 16c and d, the ratio of depolarization ratios at 1565 and 532 nm exhibits a clear height dependency. Above about 1.5 km a.g.l., the majority of the observations present a lower depolarization ratio at 1565 nm than at 532 nm, while below 1.5 km a.g.l. the depolarization ratio is higher at the longer wavelength. In previous studies (Freudenthaler et al., 2009; Groß et al., 2011; Burton et al., 2015; Haerig et al., 2017), a lower depolarization ratio at longer wavelengths has been attributed to faster removal of coarse-mode dust. However, our observations indicate the presence of a small coarse-mode, probably mineral, dust for sub-1.5 km aerosols most of the time at Limassol.

Figure 16. 2D histograms of the particle linear depolarization ratio and height at Limassol using 30 m vertical resolution smoothed by a 300 m running mean. Only data for $\sigma_\delta < 0.01$ (at the 1565 nm wavelength) are included. (a) Depolarization ratio at 532 nm. (b) Depolarization ratio at 1565 nm. (c) Ratio of depolarization ratios at 1565 and 532 nm. (d) Same as panel (c) but scaled with number of observations at each height.

4 Discussion

The majority of aerosol depolarization ratio measurements have been carried out at relatively short wavelengths (355 and 532 nm) with only a few previous studies investigating the spectral dependency including 710 nm (Freudenthaler et al., 2009; Groß et al., 2011) and/or 1064 nm (Freudenthaler et al., 2009; Burton et al., 2012, 2015; Haarig et al., 2017, 2018; Hu et al., 2019). In this study we have for the first time determined aerosol particle depolarization ratios at a wavelength of 1565 nm.

From an instrumental point of view, the Halo Doppler lidar depolarization ratio seems to be of comparable quality to the PollyXT depolarization ratio when the aerosol signal is strong. However, Halo has a much less powerful laser than PollyXT, which significantly limits the range of usable signal. On the other hand, Halo Doppler lidars are capable of independent operation for months and are therefore suitable for operational use in meteorological measurement networks.

The integration time and range gate length are adjustable in Halo firmware, and prolonging these parameters would increase the sensitivity of the system. However, high spatial and temporal resolution are preferable for utilizing the Doppler capabilities of Halo lidars. Inspecting the internal polarizer performance at liquid cloud base also requires a higher resolution. Overall, the configuration of a Halo Doppler lidar needs to be considered individually for the aims of each measurement campaign.

The spectral dependency that we observed for the 355, 532 and 1565 nm particle linear depolarization ratio agrees reasonably well with previous spectral analyses for similar aerosol types as seen in Table 2 and Fig. 17. For the mineral dust depolarization ratio, both decreasing and increasing

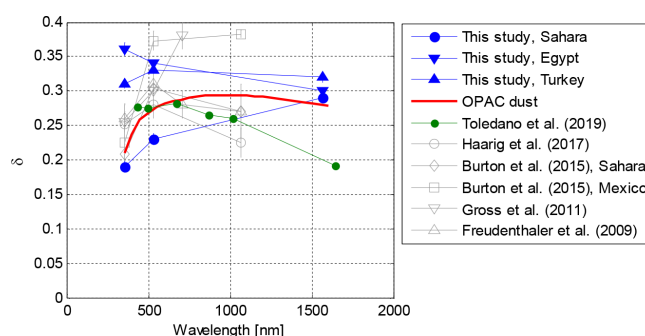

Figure 17. Particle linear depolarization ratio as a function of wavelength for dust observations in Table 2. Additionally, spectral dependency modelled with MOPSMAP based on the OPAC database for desert dust (Koepke et al., 2015; Gasteiger and Wiegner, 2018) and AERONET inversion by Toledano et al. (2019) are included.

trends with increasing wavelength have been observed previously (Table 2). This is the case for our observations at Limassol as well, though on average δ_{1565} tends to be a little lower than δ_{532} (Fig. 16). Probably, the spectral dependency of the mineral dust depolarization ratio depends on both the age of the dust and the origin of the dust. The spectral dependency of the depolarization ratio modelled with MOPSMAP (Gasteiger and Wiegner, 2018) for desert dust aerosol from the OPAC database (Koepke et al., 2015) agrees reasonably well with the Saharan dust case on 21 April 2017 in this study (Fig. 17). On the other hand, the sun-photometer-based retrieval by Toledano et al. (2019) for long-range transported Saharan dust over Barbados indicates a slightly lower depolarization ratio of 0.19 at 1640 nm compared to this study at 1565 nm (Fig. 17). The lower depolarization ratio at 1640 nm over Barbados is reasonable considering the much longer transport compared to this study.

Wavelength-dependent changes in the mineral dust depolarization ratio are small compared to elevated smoke layers, which can help to distinguish between these two aerosol types (Burton et al., 2012). For elevated smoke, a strong decrease in the depolarization ratio has been reported from >0.20 at short wavelengths to $\delta < 0.05$ at 1064 nm (Burton et al., 2015; Haarig et al., 2018; Hu et al., 2019). Thus, adding a depolarization ratio measurement at 1565 nm can provide added value to the commonly used measurements at the 355 and 532 nm wavelengths.

For marine aerosols, the depolarization ratio is small and has practically no spectral dependency (Groß et al., 2011), which is what we observed at Limassol. For the mixture of spruce and birch pollen at Vehmasmäki, the differences in the depolarization ratio at 532 and 1565 nm are small.

5 Conclusions

In this paper we report for the first time remote sensing measurements of the atmospheric aerosol particle linear depolar-

Table 2. Spectral dependency of depolarization ratio for dust, marine aerosol and pollen.

ization ratio at a wavelength of 1565 nm. Using observations at liquid cloud base we have been able to characterize the Halo Doppler lidar polarizer bleed-through with sufficient accuracy to obtain useful depolarization ratio measurements; uncertainty in the bleed-through is propagated to the depolarization ratio measurement. A comparison of two different Halo Doppler lidar systems with two PollyXT systems during collocated measurements at Limassol, Cyprus, and Kuopio – Vehmasmäki, Finland, shows good agreement between the lidar systems. The agreement between the instruments is remarkably good considering the large wavelength difference: the PollyXT depolarization ratio is retrieved at 355 and/or 532 nm. However, given the much lower laser energy in Halo Doppler lidars, it is not surprising that the vertical extent of the usable depolarization ratio is much lower than for PollyXT.

For relatively fresh mineral dust, we find particle linear depolarization ratios at 1565 nm ranging from 0.29 to 0.32, which is in good agreement with previous observations, including measurements at the 710 and 1064 nm wavelengths (Freudenthaler et al., 2009; Groß et al., 2011; Burton et al., 2015; Haarig et al., 2017). For polluted marine aerosol we observed a very low depolarization ratio of 0.009

at 1565 nm with a small decrease with increasing wavelength. The spruce and birch pollen depolarization ratio has been characterized only recently at 532 nm (Bohlmann et al., 2019). Our measurements indicate a slightly higher depolarization ratio of 0.27 at 1565 nm compared to 0.24 at 532 nm. Overall, our results indicate that Halo Doppler lidars can add another wavelength at 1565 nm to studies on the spectral dependency of the particle linear depolarization ratio, at least in the lowest 2–3 km above ground.

For aerosol typing, adding a particle linear depolarization ratio at 1565 nm to shorter wavelengths can help to distinguish biomass burning aerosols from dust, as a much stronger spectral dependency has been observed for elevated biomass burning aerosols than for dust (e.g. Haarig et al., 2017, 2018; Hu et al., 2019). In case there is prior knowledge of prevailing aerosols, such as transport of volcanic ash, even stand-alone particle linear depolarization ratio measurements with Halo Doppler lidars can probably provide useful information for aerosol typing.

Data availability. Processed lidar data are available upon request from the authors. Level 0 PollyXT observations are available at <https://polly.tropos.de/> (Polly NET, 2020, last access: 18 Au-

gust 2020). Trajectory model HYSPLIT and GDAS meteorological data are available at <https://www.ready.noaa.gov/HYSPLIT.php> (ARL, 2020, last access: 18 August 2020).

Author contributions. Conceptualization and formal analysis were carried out by VV, while investigation was carried out by HB, SB, JB, MK, RM and EJO'C. Data curation was carried out by VV, HB, SB, MK and EJO'C. VV wrote the original draft, which was reviewed and edited by VV, HB, SB, MK and EJO'C.

Competing interests. The authors declare that they have no conflict of interest.
